#### SOLID RUBBER TIRE ROLLER STUDY

#### ABSTRACT

For several years this department has been conducting research studies on the compaction of asphaltic concrete pavements to obtain maximum pavement life with available local materials. This study, done in cooperation with the Bureau of Public Roads, was to investigate the effects of the solid rubber tire roller as an intermediate roller and to compare it to the currently used high intensity pneumatic roller.

The investigation was prompted by these claims: that the solid rubber tire roller was capable of compacting the mix using higher contact pressures at higher temperatures to obtain maximum density; that it could produce equal or higher densities with fewer passes.

The basis of comparison is on data obtained during and immediately after construction, and after 6 and 24 months of service. Comparative test sections with each roller were constructed on the binder course (limited to roadway cores taken one day after compaction) and on the wearing course lift (one day, 6 months and 24 months). A contact pressure of 85 psi was used and passes were varied from 5 to 15. Comparative results for each test section consisted of percent compaction on the original cores, increases in percent compaction, measurements of longitudinal grooves, and coefficients of variation of roadway densities.

The test sections of asphaltic concrete were the Louisiana Department of Highways Type I Mix, consisting of a combination of crushed gravel, sand, mineral filler and asphalt cement. The proportions and gradations of the mix are shown in Tables 1, 2 and 4 of the appendix.

Results reported here are based on findings from these procedures and are confined to the materials and conditions under study.

#### SUMMARY OF RESULTS

- 1) Both rollers were found to be equally capable of compacting asphaltic concrete pavements. Twenty-four months service did not change the visual appearance of the test sections, and there was no significant difference between the test sections compacted by either roller.
- 2) The average compaction results for both the pneumatic and solid rubber tire roller sections were approximately equal, and both met the minimum specification requirement of 95 percent.
- 3) Both roller sections had a 2.4 percent average differential increase in compaction after 24 months of service, with 2.2 percent occurring in the first six months.
- 4) Longitudinal grooves of 4 to 5 millimeters in depth were equal for both roller sections after six months of traffic. Additional increases from 6 to 24 months averaged less than 0.5 millimeters.
- 5) The average coefficient of variation of roadway densities on the binder course was 0.36% for the pneumatic roller and 0.34% for the solid rubber tire roller. On the wearing course the averages were 0.18% and 0.19% respectively.
- 6) Best initial rolling temperatures at a contact pressure of 85 psi on the binder course were 200°F for the pneumatic roller and 180°F for the solid rubber tire roller and 185°F and 175°F respectively on the wearing course.
- 7) Both the pneumatic and solid rubber tire rollers required the same number of passes to acquire optimum compaction.

#### METHO DOLOGY

#### Field Control During Construction

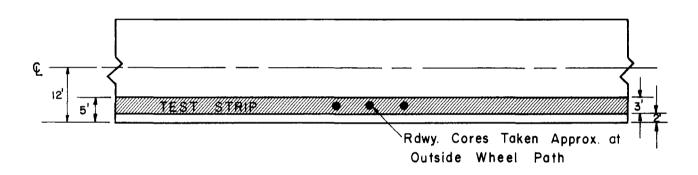

Section Numbers

6 A-B-C

Thirty-six separate test sections were constructed on State Project 13-09-22, FAP F 128 (6), on La. U. S. Highway 190 (Hammond-Goodbee), which had an average daily traffic of 5,600. The three wheel roller, the solid rubber tire or pneumatic roller and the tandem roller were used in a sequence. Contact pressures were 85 psi.

The number of passes of the rollers was carefully controlled on each test section. A test strip was used rather then the entire 12 foot lane to prevent overlapping of the roller passes. All roadway cores were taken within the limits of the test strip.

Diagram of Test Strip

Temperatures were recorded on each test section on the loose mix as it was dumped into the spreader box by a dial thermometer and before and after each sequence of rolling by a Leeds and Northrup Potentiometer.

Triplicate test sections were constructed to eliminate the results of sections having inconsistent gradations. The test sections were designated as follows:

Bootton mannote		
Pneumatic Roller	Solid Rubber Tire Roller	Number of Passes
1 A-B-C	7 A-B-C	5
2 A-B-C	8 A-B-C	7
3 A-B-C	9 A-B-C	9
4 A-B-C	10 A-B-C	11
5 A-B-C	11 A-B-C	1 3

12 A-B-C

15

The numbers represent sections taken from both binder and wearing course lifts; however, sections 1-12 A-B-C of the binder course were at different locations from sections 1-12 A-B-C of the wearing course.

#### Plant Control During Construction

Six sets of specimens, using 75 blows on each face with a standard Marshall hammer, were molded per day. Each set consisted of duplicate specimens. Two loose mix samples were obtained each day for gradation and bitumen content determination. The Marshall specimens and the loose mix samples were tested according to the following procedures:

Designation

Method of Test	Designation
1) Determination of Specific Gravity of Compressed Bituminous Mixtures	LDH TR 304-66
2) Method of Test for the Stability and Flow of Asphaltic Concrete Mixtures- Marshall Method	LDH TR 305-66
3) Method of Test for Bitumen Content of Paving Mixtures by Reflux Extractor	LDH TR 307-66
4) Method of Test for Mechanical Analysis of Extracted Aggregate	LDH TR 309-64

#### Description of Rollers

Method of Test

Some of the basic specifications for the pneumatic and solid rubber tire rollers are as follows:

	Solid Rubber Tire	Pneumatic
Type	Buffalo Springfield PSR-14 SR	Ingram
Tires	Solid Rubber 30 by 9	900-20, 14 ply
Rolling Width	68 in.	96 in.
Wet Ballasted	28,000 lbs	55,000 lbs.
Maximum Contact Pressure	117 psi	92 psi.

The pneumatic roller used in this study was 96 in. wide, and the solid rubber are roller was only 68 in. wide. The larger width of the pneumatic roller has the dvantage of requiring less passes to cover the entire width of the roadway, but disadvantage of not being as easy to operate as the smaller rubber tire roller.

important advantage of the pneumatic tire over the solid rubber tire is that the **exact pressures** may be varied by simply inflating or deflating the tires. To

vary the contact pressure of the solid rubber tire, it is necessary to load or unload ballast from the roller, which is a much more difficult and time consuming operation. However, the solid rubber tire should have a more consistent contact pressure during the rolling procedures.

Figures 1, 2 and 3 illustrate the pneumatic and solid rubber tire rollers used in this study.

#### DISCUSSION OF RESULTS

Although advantages and disadvantages of each roller have been mentioned, the primary basis for comparison should be results obtained during and after construction. All individual and average results are in the appendix.

#### Binder Course

Figure 4 represents the average percent compaction versus the number of passes of the rollers on a binder course lift at 4.5 percent asphalt content. It indicates that the pneumatic roller results gave a more logical compaction curve than the solid rubber tire roller results. The reason for this has not been determined. Each point on the curve represents an average of six roadway cores taken at two separate locations. The possibility of a change in gradation or rolling temperatures could result in such irregularity; however, the same procedure was carried out for the pneumatic roller sections.

Figure 5 shows similar results for a binder course lift at 4.7 percent asphalt content.

Rolling of the pneumatic sections for the binder course began at 200°F and at 180°F for the solid rubber tire sections. This differential occurred due to the solid rubber tire's inability to effectively roll the mix at 200°F without inducing excessive rutting and shoving. This contradicts the claim that the solid rubber tire roller was capable of rolling the mix at higher temperatures.

#### Wearing Course

The number of passes on the test sections were varied with each roller to evaluate the compactive effort required to obtain maximum density.

Figure 6 shows the average percent compaction versus the number of roller passes. Each point is an average of nine roadway cores. The results were similar for both rollers, although the original compaction was approximately 0.9 percent higher for the solid rubber tire sections. The most effective rolling temperatures were 185°F for the pneumatic roller and 175°F for the solid rubber tire roller.

The trend of the curves was approximately the same after 6 and 24 months of

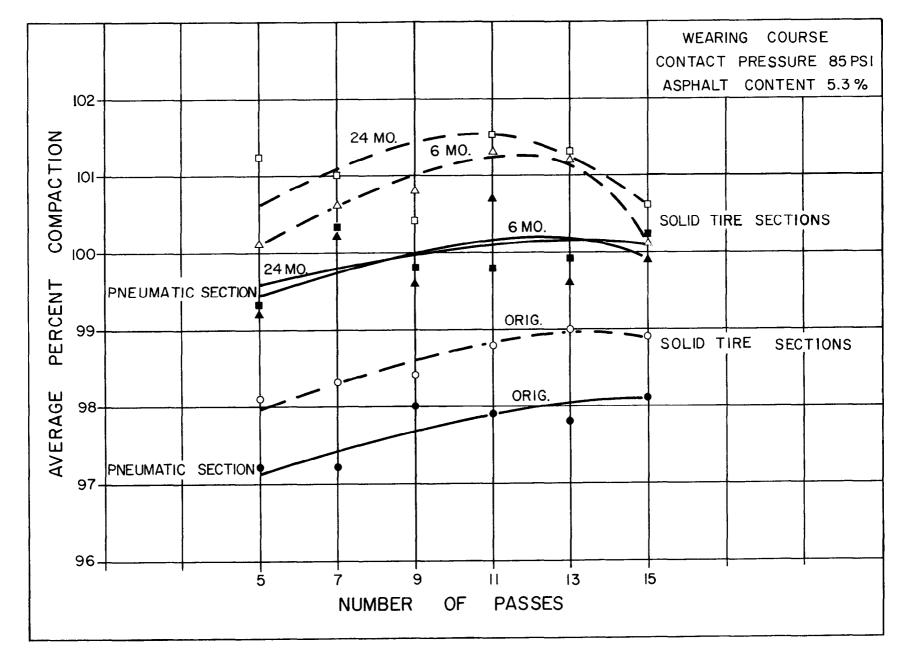

Figure 6 - The Average Percent Compaction Versus Number of Passes Relationship on the Wearing Course for the Original, 6 month and 24 month results for the Pneumatic and Solid Tire Sections.

service; however, higher percent compaction was obtained due to traffic densification.

At optimum conditions of the compactive effort the least increase in compaction due to traffic and the least change in voids over a period of time may be expected. This is more easily substantiated where there is a significant difference in percent compaction from the optimum. In this study the greatest change in the original percent compaction between the lowest average value of 97.2 and the highest of 99 was only 1.7 percent, which is not a significant difference.

Figure 7 represents the average percent voids versus time at the optimum of 15 passes with both rollers. The trend of the curves was almost identical for both rollers up to 24 months. The largest decrease in voids due to traffic densification occurred after six months for both roller sections. This would indicate that the largest increase in compaction and in longitudinal grooves would also occur after six months of service.

Figure 8 is a graphical representation of the differential increase in percent compaction after 24 months of service. Approximately 92 percent of this increase occurred within the first six months. The average differential increase in compaction was approximately the same for both rollers.

Figure 9 shows a graphical representation of the number of passes versus the average longitudinal grooves. The graph indicated that the highest average longitudinal grooves of five millimeters were equal for both rollers after 24 months of service. The average grooves on both roller sections were approximately equal after six months, with the exception of the 13 and 15 pass solid rubber tire sections which were one millimeter lower than the corresponding pneumatic sections. The only change from 6 to 24 months was a one millimeter increase in grooves on the solid tire sections at 5 and 15 passes, indicating that practically all rutting had taken place during the first six months of traffic.

#### Variations of Roadway Density Results

The results discussed thus far on the binder and wearing course lifts are the average of the duplicate or triplicate test sections previously mentioned. The validity of these averages depends primarily on the variations of roadway densities of the similar sections and on the variations of the individual density results within the sections.

Figures 10 and 11 represent the average coefficient of variation versus the number of passes for the binder and wearing courses. The variation of the individual sections are listed in Tables 23 and 24 of the appendix. The coefficients were plotted in percentages and were calculated from the roadway density data (lb.per cu. ft.).

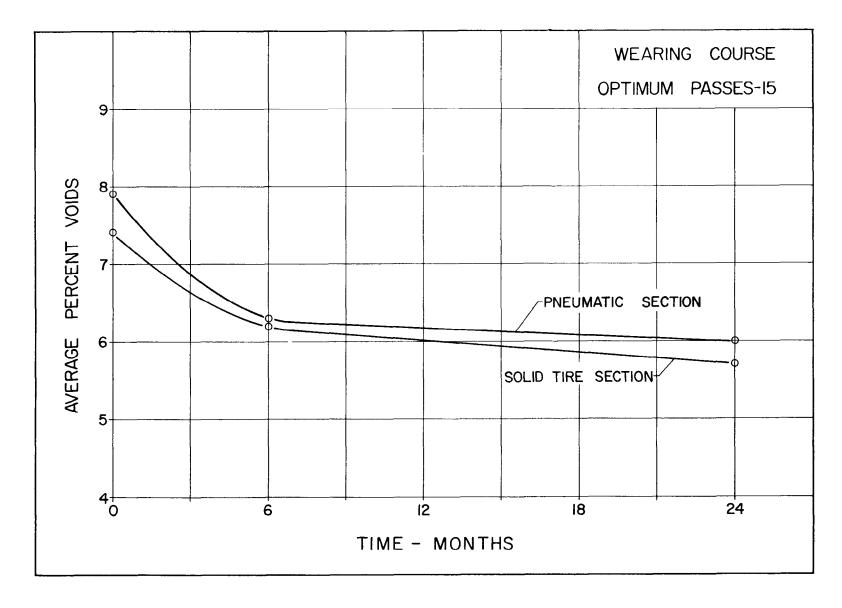

Figure 7 - The Average Percent Voids Versus Time Relationship for the Pneumatic and Solid Tire Sections Constructed at the Optimum of 15 passes.

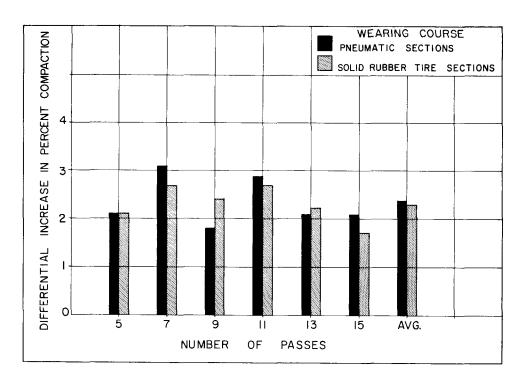

Figure 8 - A Graphical Representation of the Differential Increase in Percent Compaction from the Original to 24 months versus Number of Passes for the Pneumatic and Solid Tire Sections.

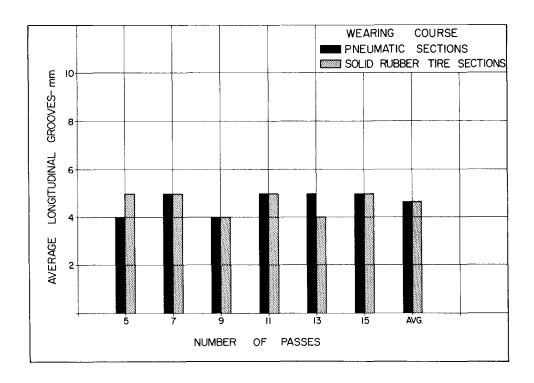

Figure 9 - A Graphical Representation of the Longitudinal Grooves After 24 Months of Service, versus Number of Passes for the Pneumatic and Solid Tire Sections.

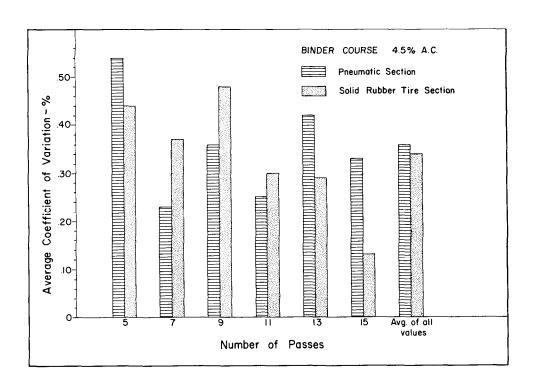

Figure 10 - The Average Coefficient of Variation of Roadway Densities versus Number of Passes for the Pneumatic and Solid Tire Binder Course Sections.

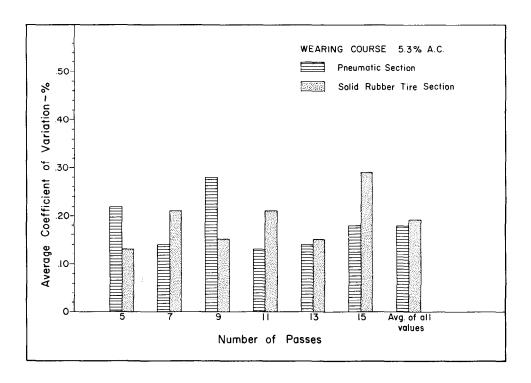

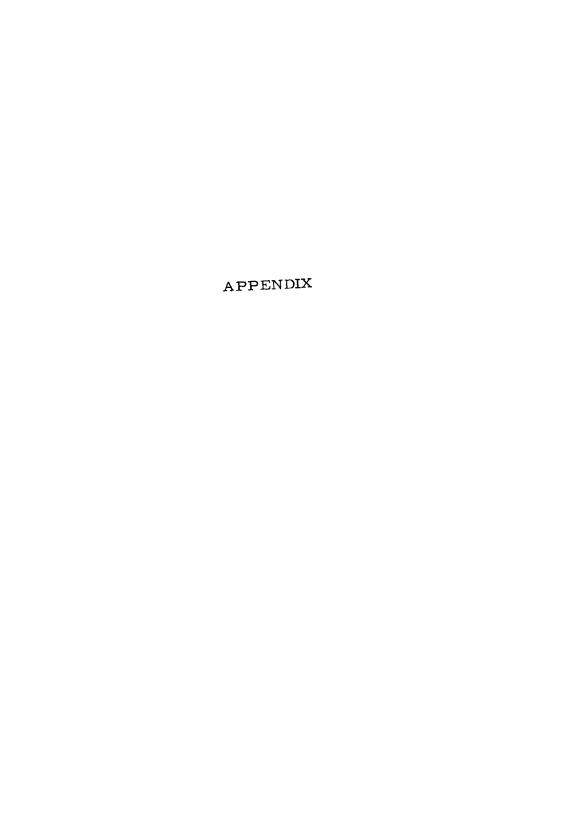

Figure 11 - The Average Coefficient of Variation of Roadway Densities versus Number of Passes for the Pneumatic and Solid Tire Wearing Course Sections.

Results indicate that the average coefficient of variation for all sections were approximately equal for both rollers on the binder and wearing course lifts. Of the two lifts, the wearing course showed the least variation in roadway density.

The differences in results in the comparison of the pneumatic and solid rubber tire rollers are minimal and do not justify recommending one roller over the other for compacting asphaltic concrete mixtures.
